Abstract

The Taj Mahal—an iconic World Heritage monument built of white marble—has become discolored with time, due, in part, to high levels of particulate matter (PM) soiling its surface (Bergin et al. 2015 Environ. Sci. Technol. 49 808–812). Such discoloration has required extensive and costly treatment (2015 Two Hundred Sixty Second Report on Effects of Pollution on Taj Parliament of India Rajya Sabha, New Delhi) and despite previous interventions to reduce pollution in its vicinity, the haze and darkening persists (Bergin et al. 2015 Environ. Sci. Technol. 49 808–812; 2015 Two Hundred Sixty Second Report on Effects of Pollution on Taj Parliament of India Rajya Sabha, New Delhi). PM responsible for the soiling has been attributed to a variety of sources including industrial emissions, vehicular exhaust and biomass burning, but the contribution of the emissions from the burning of open municipal solid waste (MSW) may also play an important role. A recent source apportionment study of fine particulate matter (PM 2.5 ) at the Taj Mahal showed biomass burning emissions, which would include MSW emissions, accounted for nearly 40% of organic matter (OM)—a component of PM—deposition to its surface (Bergin et al. 2015 Environ. Sci. Technol. 49 808–812); dung cake burning, used extensively for cooking in the region, was the suggested culprit and banned within the city limits (2015 Two Hundred Sixty Second Report on Effects of Pollution on Taj Parliament of India Rajya Sabha, New Delhi), although the burning of MSW, a ubiquitous practice in the area (Nagpure et al. 2015 Environ. Sci. Technol. 49 12904–12), may play a more important role in local air quality. Using spatially detailed emission estimates and air quality modeling, we find that open MSW burning leads to about 150 (±130) mg m −2 yr −1 of PM 2.5 being deposited to the surface of the Taj Mahal compared to about 12 (±3.2) mg m −2 yr −1 from dung cake burning. Those two sources, combined, also lead to an estimated 713 (377–1050) premature mortalities in Agra each year, dominated by waste burning in socioeconomically lower status neighborhoods. An effective MSW management strategy would reduce soiling of the Taj Mahal, improve human health, and have additional aesthetic benefits.

Introduction

The Taj Mahal in Agra, India is a UNESCO World Heritage Site that attracts millions of tourists each year. However, its surface has been soiled over time, discoloring its white marble façade. Studies have recognized that poor air quality is responsible for the soiling and discoloration [1, 4−7] and measures have been taken to curb the impact of local air pollution around the Taj Mahal including restricting vehicles
near the complex, closing over 200 enterprises in Agra, requiring iron foundries to install scrubbers and filters on their smokestacks, prohibiting new polluting enterprises from being built within a defined buffer zone around the mausoleum, and most recently, banning cow dung cake burning as cooking fuel [2]. A recent source apportionment study of fine particulate matter (PM$_{2.5}$, whose particles are less than 2.5 μm in aerodynamic diameter) at the Taj Mahal found that biomass burning accounts for nearly 40% of all organic matter (OM) deposition to its surface [1]. Two sources of biomass burning PM$_{2.5}$ in Agra, which would be included in the measurement of deposited OM, are the open combustion of municipal solid waste (MSW) and dung cake burning [3]. The high particulate matter (PM) loadings in Agra also reduce visibility, further impairing the aesthetic beauty of the Taj Mahal.

While the discoloration of the Taj Mahal and the deterioration of visibility may be the most immediately noticeable outcome of MSW and dung cake burning in the area, human health is of concern as well. The Global Burden of Disease (GBD) found that of 67 environmental factors associated with premature mortality, exposure to ambient PM pollution is the 5th leading cause of premature mortality in India after high blood pressure, indoor air pollution (which is also affected by dung cake burning), smoking and dietary risks [8]. Additionally, residential and commercial energy use, including biomass burning used for heating and cooking, is responsible for the largest impact on mortality linked to outdoor air pollution throughout India [9].

Rapid growth in Agra, coupled with a limited MSW management infrastructure, has resulted in less effective waste management that leaves large volumes of trash accumulating in the streets [3, 10]. Further, generated waste is openly and frequently burned on roadsides and in residential and commercial areas in Agra [3] and throughout India [10], leading to byproducts of poor combustion and increased pollutant emissions [11–13]. The Central Pollution Control Board of India estimated MSW-burning to contribute between 5% and 11% of primary PM emissions from sources within cities [14]. MSW emissions include combustion byproducts of plastics and other waste in addition to biomass, which can contain chlorinated organics, dioxins, polycyclic aromatic hydrocarbons (PAHs), numerous volatile organic compounds (VOCs) and heavy metals including lead, cadmium and mercury [15, 16]. Health impacts specific to these toxic compounds are not specifically addressed in the GBD approach.

Dung cake burning used as cooking fuel has been more studied in Indian cities [17–19]; 11% of rural Indian households depend on cow dung as their primary cooking fuel [19]. Open MSW burning and dung cake burning tends to be more concentrated in areas of poorer populations [3, 20–24], exacerbating exposures to more vulnerable populations. MSW and dung cake emissions can also influence radiative balance and lead to regional and global change [11, 25, 26].

In this paper, the contributions of MSW and dung cake burning to ambient OM and BC (pollutants known to discolor surfaces [27]) concentrations in Agra, the deposition to and soiling of the Taj Mahal, and health impacts are assessed by quantifying location-specific MSW and dung cake burning emissions, performing air quality and deposition modeling, and conducting a health impact assessment. Such information can be used to evaluate the potential benefits of policy interventions, including improved MSW collection management practices and the associated infrastructure in and around Agra.

**Methods**

**Open MSW and dung cake burning inventories**

Waste burn rate inventories were generated in Agra using a recently developed field transect approach to quantify the spatial and temporal trends of open MSW burning [3]. In this method, researchers move along the transect (route/line) and record burning incidents, approximate weight, and composition of MSW in a predetermined distance from the line of the transect (route/line) (typically visible range is used as the distance). MSW burning incident density is then estimated by the total MSW burning incidents count and surveyed area. Two separate transect routes in Agra that covered 35 and 45 km$^2$, respectively (SI figures 1 and 2), were used in this study over three days for each route between 30 May and 2 Jun, 2015 to quantify the waste burn density, composition, and the mass of waste burn. These surveys assessed MSW burning by socioeconomic status (SES) based on census data [18] at the neighborhood level and represented 14 neighborhoods of different SES (SI figure 1). Satellite-driven studies at the global scale cannot capture the very high levels of waste burning found in neighborhoods or near roads [9], thus the on-ground field approach is an important part of developing an improved PM emission inventory from MSW burning.

The open waste burn rate, TWB$_i$ (g-MSW day$^{-1}$), within an electoral ward, $i$, from the SES-based waste burning rates is quantified by:

$$\text{TWB}_i = \text{WBR}_{\text{low SES}} \times \text{POP}_{\text{low SES}} + \text{WBR}_{\text{high SES}} \times (1 - \text{POP}_{\text{low SES}})$$  

(1)

where WBR$_{\text{low SES}}$ = daily per capita waste burn rate of the low SES, POP$_{\text{low SES}}$ = illiterate population within the ward as reported in the 2011 census [18], and WBR$_{\text{high SES}}$ = daily per capita waste burn of the high SES. Literacy was the primary indicator of SES used in this study; the total reported literacy rate in Agra is 64% [18]. Waste burn inventories were generated on an electoral ward basis and each ward
was modeled as its own emission grid, as were five additional zones (SI figure 3).

Data on the use of cow-dung cakes as fuel for food preparation data was assessed from the census [18]. The census gave the percentage of households at the ward/precinct level using different types of fuel for cooking. Annual per household consumption of cow dung was then multiplied with the number of households using cow dung as a fuel for cooking (SI figure 4) within each ward/precinct to determine electoral-ward based burning inventories, computed on an annual basis and then converted to daily average emission rates. Applying the same method, air quality impacts from two additional sources, firewood and crop residue, were also modeled for comparison.

**MSW and dung cake burn inventories to AERMOD dispersion modeling**

Open MSW and dung cake burn rates were applied in AERMOD, a Gaussian plume dispersion model [28], to spatially characterize the ambient, annually averaged PM$_{2.5}$ concentrations from MSW and dung cake burning. AERMOD is a recommended regulatory air pollution dispersion model, but has limitations as it does not include atmospheric chemical processes or secondary pollution formation [28]. The findings presented here are specific source impacts from emissions within the study domain, i.e., background transport is not considered. Integrated hourly surface data from the National Climatic Data Center (NCDC) at the Agra Station from the National Oceanic and Atmospheric Administration (NOAA) and upper air data from the US National Weather Service (NWS) at the Delhi Station were used in AERMOD, a meteorological input to AERMOD. Digital Elevation Models from the Global 30 Arc-Second Elevation (GTOPO30) were used in AERMAP, a terrain processing input to AERMOD.

OM and BC source emission rates from both MSW and dung cake burning were determined using emission factors from the literature [29, 30] (SI table 2). PM$_{2.5}$ component-specific emission factors for MSW burning used here are from measurements of trash burning in peri-urban communities near Mexico City at varying combustion stages [29]. Christian et al [29] found emission factors of OC = 5.3 (±4.9) and BC = 0.65 (±0.27) g kg$^{-1}$ burned. These emission factors are within the reported range of 0.04–9.97 g BC kg$^{-1}$ burned from recent measurements of trash burning in Nepal where some samples were enriched for specific compositions of plastic and foil [31], but lower than the reported range of 8.4–73.9 g OC kg$^{-1}$ burned. MSW emissions can vary significantly and have high uncertainties due to the composition of the waste and stage of combustion [13, 32]. Emission factors applied for dung cake burning were measured in households throughout the Indo-Gangetic Plain [30]. An OM/OC factor of 2.1 [33] was applied to the OC emission factors; OM is related to OC as the former accounts for specific elements other than carbon associated with the organic compounds.

**Human health risk assessment from open MSW and dung cake burning emissions**

Premature mortality attributable to PM$_{2.5}$ (BC + OM) emissions from MSW and cow dung cake burning were determined using concentration response function (CRFs) based equations. Five major diseases—acute respiratory lung infection (ALRI), chronic obstructive pulmonary disease (COPD), ischemic heart disease (IHD), cerebrovascular disease (stroke) and lung cancer (LC)—associated with PM$_{2.5}$ mortality risks were assessed in this study. COPD, IHD, stroke, and LC related mortality were determined for adults (age ≥ 25 years), while mortalities related to ALRI were estimated for children under five years of age. Disease-specific relative risk equations use a CRF, incidence rate for premature mortality, change (increment) in ambient pollution concentration, and exposed population to estimate the mortality. The CRFs data and equation (2) used integrated-exposure response functions (IERs) to estimate specific health impacts [34].

\[
RR = 1 + a \left\{ 1 - \exp \left[ -b \left( \Delta C \right)^p \right] \right\}, \quad \text{for } C > C_0
\]
\[
RR = 1, \quad \text{for } C \leq C_0
\]

(2)

\[
PAF = \frac{\sum_{i=1}^{n} P_i (RR_i - 1)}{\sum_{i=1}^{n} P_i (RR_i - 1) + 1}
\]

(3)

\[
P_h = B_i \cdot PAF \cdot P_o
\]

(4)

where RR is the relative risk or CRFs, $\Delta C$ is the increase of ambient PM$_{2.5}$ concentrations due to dung cake and MSW burning emissions, $C_0$ is the baseline PM$_{2.5}$ concentration (considered 0 for this source impact application), and $a$, $b$, and $p$ are parameters that determine the relationship of concentration to response and are discussed further in Burnett et al 2014 [34]. PAF is the population attributable fraction, i.e., the proportion of the disease incidence on the exposed population that can be attributed to the exposure, $P_i$ is the fraction of the population in exposure category, $i$, and $n$ is the number of exposure categories, where exposure categories were defined by five-year age increments with available CRFs. $P_h$ is the premature mortality associated with PM$_{2.5}$ exposure and $B_i$ is the baseline population incidence of given health effects (i.e. death per 100 000). The exposed population within each modeling grid was retrieved from the 2015 Worldpop Database. A growth factor for the total population within the study domain for the Worldpop Database reported population compared to the 2014 projected population from the census [18] was used, as the modeling results presented are for 2014.

Also determined were disability adjusted life years (DALY), which estimate the current discounted value
of future years of health life lost due to morbidity and future year of human years of life lost (YLL) due to premature mortality. Since air pollutants are not a primary cause of mortality, but rather contributory, DALY can be a better indicator of health risks than premature mortality [35]. The DALYs are calculated as the total of the YLL due to premature mortality and years lost due to disability (YLD) because of morbidity. In this study we only estimated the premature deaths due to PM$_{2.5}$ emissions associated with biomass and MSW burning and thus considered YLL as the measure of DALYs. YLL were calculated using the following equation:

$$YLL = B_i \times PAF \times POP_i \times LE,$$

where $POP_i$ is the exposed population (i.e., the population within each modeled grid) and $LE$ is the standard life expectancy at age of death (in years).

**Dry deposition to and pollutant covering of the Taj Mahal**

Pollutant deposition to the surface of the Taj Mahal contributes to its browning [1], so the impacts of wet and dry deposition from MSW and dung cake emissions were quantified. Dry deposition rates were calculated using modeled concentrations, measured size distributions and size-dependent deposition velocities. Deposition velocity is a variable that incorporates the aerodynamic transport through the atmospheric surface layer, the transport across the quasi-laminar sublayer, and the uptake at the surface into a single parameter [36, 37]. Imaging from a scanning electron microscopy (SEM) (LEO 1530, Carl Zeiss Microscopy) and energy dispersive x-ray spectroscopy (Oxford Instruments X-Max detectors) were used to measure the average particle size of carbonaceous PM species at the surface of the Taj Mahal [1]. The average particle size was found to be $\sim 1 \mu m$.

The PM$_{2.5}$ component specific mass fluxes (g m$^{-2}$ s$^{-1}$), $F_i$, of OM and BC to the surface of the Taj Mahal by dry deposition were found as:

$$F_i = -V_{d,i}(d_{p,ave}) \times \frac{[C_i(t)]}{d_{p,ave}},$$

where $V_{d,i}$ is the size-specific surface deposition velocity (m s$^{-1}$) and $d_{p,ave}$ is the average particle diameter. The pollutant concentration, $[C_i(t)]$, used here is the annual average, ambient pollutant concentration from open waste and dung cake burning at the Taj Mahal as determined in AERMOD. Wet deposition was considered in this analysis to account for rain, and the wet deposition loadings were small compared to dry deposition (see SI section 3 for a detailed assessment).

The fraction of the Taj Mahal’s surface covered by pollutant deposition from MSW and dung cake burning emissions was also quantified from the modeled number of particles deposited per area of the surface and the total surface area of the aerosol deposited per area of the surface. The number of particles per unit area (particles m$^{-2}$), $N_i$, from each source and pollutant, $i$, was determined by:

$$N_i = \frac{\sigma_i}{\rho_i d_{p,ave} \times 6},$$

where $\sigma_i$ (mg m$^{-2}$ yr$^{-1}$) is the specific pollutant loading for each source, $\rho_i$ is the pollutant (OM or BC) density [38, 39], and $d_{p,ave}$ is the average particle diameter from on-site measurements ($\sim 1 \mu m$).

Combined with the average surface area per particle, the fractional cover of PM$_{2.5}$ emissions from MSW and dung cake burning in one year, $\Omega_i$, was then calculated as:

$$\Omega_i = \frac{6 \sigma_i}{\rho_i d_{p,ave}}.$$

**Results and discussion**

Open MSW and dung cake burning emissions to modeled concentrations throughout Agra and model evaluation

Employing the field transect method developed by Nagpure et al [3], the total average waste burn rate in Agra was estimated at 130 g MSW capita$^{-1}$ day$^{-1}$ with higher per capita burn rates observed in low SES areas (table 1). Burn rates were higher in the morning than the evening within the city, but showed less diurnal difference in the rural areas (areas outside of the city boundaries). If Agra’s per capita average waste burn rate is applied to the entire population of India, the annual nationwide burn rate would be 68000 Gg yr$^{-1}$, consistent with model findings of Wiedinmyer et al of 35000–75000 Gg yr$^{-1}$ for India [40]. The total cow dung cake burning emissions on a ward-by-ward basis within Agra were calculated from household fuel use data [17, 18] (SI figure 4) and ranged between 0–9100 kg day$^{-1}$ ward$^{-1}$ within the study domain, compared to 490–25000 kg day$^{-1}$ ward$^{-1}$ from open waste burning (SI table 1). A report on sustainable solid waste management in India reported the average waste generation rate in Agra as 580 g MSW capita$^{-1}$ day$^{-1}$ [41]. Applying this MSW generation rate, the average burn rate of MSW in Agra is 23%, higher than the 5%–10% estimates from previous waste burning studies in Indian cities [10, 42, 43].

Applying emission factors from the literature [29, 30] in conjunction with observed burn rates resulted in annual combined emissions in Agra from open waste and dung burning to be 2500 (±2200) kg yr$^{-1}$ and 150 (±58) kg yr$^{-1}$ for the OM and BC components of PM$_{2.5}$, respectively. Annual average PM$_{2.5}$ component concentrations due to open waste and dung cake burning throughout Agra, simulated by AERMOD, found concentrations at the Taj Mahal to be 4.1 (±3.8) and 0.24 (±0.10) µg m$^{-3}$ for OM and BC from MSW burning and 0.32 (±9.1 × 10$^{-2}$) and 0.019 (±9.7 × 10$^{-3}$) µg m$^{-3}$ for OM and BC from
dung cake burning (figure 1 and SI figure 5). Uncertainty was assessed just for the emission factors as that is where much of the uncertainty lies due to variations in waste composition and stage of combustion. The calculation does not consider secondary formation of PM$_{2.5}$ due to gaseous emissions from those sources. These results were evaluated using measurements from a recent PM$_{2.5}$ source apportionment study at the Taj Mahal that found that the contribution of biomass burning emissions to OM (which can be from a variety of combustion activities including wood, crop, dung and MSW burning) at the Taj Mahal to be 12 $\mu$g m$^{-3}$ [1]. While the sum of the four sources assessed here (MSW, dung cake, firewood, and crop residue) is 5.9 ($\pm$4.7) $\mu$g m$^{-3}$, suggesting regional transport of additional OM, MSW is the highest contributor of modeled biomass burning sources (SI figure 6).

Maximum combined annual-averaged impacts on PM$_{2.5}$ in Agra were 33 ($\pm$30) $\mu$g m$^{-3}$ from MSW burning and 3.3 ($\pm$0.90) $\mu$g m$^{-3}$ from dung cake burning (figure 1 and SI figure 7). High levels were found in neighborhoods with lower SES where MSW and dung-cake burning are most prevalent. The contribution from open MSW burning is greater than for dung cake burning throughout Agra, except in the rural areas where dung cake burning is a primary fuel source for cooking [17, 18]. The combined annually-averaged ambient PM$_{2.5}$ concentration averaged throughout Agra from open waste and dung cake burning was 4.3 ($\pm$3.8) $\mu$g m$^{-3}$ for OM and 0.25 ($\pm$0.10) $\mu$g m$^{-3}$ for BC. Recent ambient OC and elemental carbon concentration measurements throughout Agra have been reported between 10.2 ($\pm$7.2)–30 ($\pm$13) $\mu$g m$^{-3}$ and 1.3 ($\pm$0.8)–4.0 ($\pm$1.5) $\mu$g m$^{-3}$ [32, 44], which suggest the source impact modeling results averaged over the study domain are in line with ambient measurements.

### Table 1. Diurnal per capita open MSW burn rates (g capita$^{-1}$ day$^{-1}$) in Agra categorized by socioeconomic status (SES) using a recently developed field transect approach [2]. Higher per capita open waste burn rates were observed in regions of lower SES.

Conclusions and implications

Our model finds that open MSW-burning and dung cake burning led to estimated PM$_{2.5}$ impacts of 4.3 and 0.34 $\mu$g m$^{-3}$ (annually averaged) at the Taj Mahal, respectively, and up to 33 and 3.3 $\mu$g m$^{-3}$ in Agra, with...
the highest levels in low SES neighborhoods. The increased OM and BC PM$_{2.5}$ from those sources at the Taj Mahal lead to an increase of 160 mg m$^{-2}$ yr$^{-1}$ of PM$_{2.5}$ deposition to its surface, 150 mg m$^{-2}$ yr$^{-1}$ from open waste burning and 12 mg m$^{-2}$ yr$^{-1}$ from dung cake burning. The amount of PM$_{2.5}$ deposited, along with the optical characteristics of the particles [1, 11, 13] lead to substantial soiling and discoloration of the Taj Mahal, and also reduced visibility, further degrading the aesthetic beauty of the site. A population, concentration-weighted exposure and health assessment finds that chronic exposure to MSW and dung burning related ambient PM$_{2.5}$ was found to increase premature deaths by approximately 713 per year. While more difficult to quantify, acute exposures to the high PM$_{2.5}$ levels can have additional health impacts, e.g., to visitors.

Potential interventions can address the soiling of the Taj Mahal, degraded visibility, and human health in the area. In addition to improving ambient air quality, the recently promulgated ban on dung cake burning can improve indoor air quality, magnifying the estimated health benefits beyond those found based on improving ambient air quality alone. However, the benefits from its proposed implementation will be dependent upon more than 50,000 homes using cleaner sources for cooking [51, 52]. Better MSW management and prevention of garbage burning in Agra were explored previously [53] but were not considered as high impact options to protect the Taj Mahal and public health. This paper indicates that preventing MSW burning can have a higher impact compared to the recently enacted dung cake burning ban on reducing PM$_{2.5}$ concentrations affecting health and PM$_{2.5}$ deposition that soils the Taj Mahal. Policies and action to reduce MSW burning should therefore be considered in the portfolio of actions to preserve the Taj and improve urban public health in Agra, particularly in low SES areas where people are disproportionately exposed to MSW and dung cake burning emissions.

Interventions leading to better waste management have not been a high priority in previous efforts to address air pollution in Indian cities. Agra Municipality has shown the initiative to implement policies designed to reduce soiling of the Taj Mahal, including limiting mobile source emissions near the landmark, banning polluting enterprises nearby, and prohibiting dung cake burning. Our results suggest that implementing a better waste management infrastructure [53] can be a high impact action that can improve ambient air quality in Agra, decrease soiling of the Taj Mahal and reduce adverse health outcomes.

Acknowledgments

This work was supported by NSF PIRE Grant No. 1243535, NSF SRN Grant No. 1444745, USAID PEER, and instruments were available from grants from the Ministry of Human Resource Department (3-21/2014-TS.1), Government of India and IIT-K grant for PG Teaching and Research. In addition, Cesunica Ivey at Georgia Institute of Technology contributed to the model development. Fernando Garcia Menendez at Massachusetts Institute of Technology provided ArcGIS files for emission grids. Heidi Vreeland at Duke University assisted with creating figures for
publication. Vipul Lalchandani and Shamjad PM assisted with field work and data collection in Kanpur. Gratitude is expressed toward Prakash Bhave of ICIMOD, Robert Yokelson at the University of Montana and Elizabeth Stone at the University of Iowa for providing detailed data for past and in progress studies. Further methods explanations and data are available in the Supplementary Information. Correspondence and requests for materials should be addressed to Armistead Russell (ted.russell@gatech.edu) and Sachchida Tripathi (snt@iitk.ic.in).

Author contributions

AGR, MHB, AR, SNT planned the research. RML, LL developed the models applied in the study and quantified the surface deposition. ASN, AR, MHB developed the waste burning inventory methodology. ASN, RML conducted the on-site waste burn sampling, developed the emissions inventories, and performed the health impact assessments. MHB and SNT performed on-site detailed particle size measurements. RML, ASN, AGR wrote the manuscript.
